

LIQUID CRYSTAL DISPLAY APPARATUS AND METHOD OF DRIVING THE SAME

5

BACKGROUND OF THE INVENTION

(a) Field of the Invention

The present invention relates to a liquid crystal display apparatus and a method of driving the same, and more particularly to a method of driving a liquid crystal display element which provides high contrast and high brightness and which is not affected by electrical asymmetry, as well as a liquid crystal display apparatus having a liquid crystal display element that is driven by such a method.

15

(b) Description of the Related Art

The mainstream of a high performance liquid crystal display apparatus is a TFT (thin-film transistor)-scheme active matrix liquid crystal display apparatus of a TN (twisted nematic) mode using nematic liquid crystal or an IPS (in-plane switching) mode. In such an active matrix liquid crystal display apparatus, an image is re-displayed at 60 Hz, because positive and negative image signals are written at 30 Hz, making the time period of one field about 16.7 ms (millisecond). The total of the time for

25

writing the positive image signal and the time for writing the negative image signal is called a frame time, which is about 33.3 ms. By contrast, the response time of the fastest available liquid crystal is almost equal to the frame time. Therefore, display of an image including a motion picture or display of a high speed computer image requires a response speed faster than the current frame time.

Meanwhile, a field-sequential color liquid crystal display apparatus has been studied in an effort to increase resolution. In the field-sequential color liquid crystal display apparatus, the color of a back light of the liquid crystal display apparatus is sequentially switched among red, green, and blue. Since this method does not require that color filters be spatially disposed, the resolution can be increased to three times that of a conventional liquid crystal display apparatus. In the field-sequential color liquid crystal display apparatus, since an image for one color must be displayed within a period $1/3$ that for one field, the time period that can be used for display is about 5 ms. Therefore, liquid crystal itself is required to have a response time shorter than 5 ms. Liquid crystal that causes spontaneous polarization, such as ferroelectric liquid crystal or antiferroelectric liquid crystal, has been studied as candidate liquid crystal

capable of achieving such a high response speed. Further, in relation to nematic liquid crystal, various studies have been performed in an effort to improve a response speed through an increase in the degree of dielectric anisotropy, a decrease in viscosity and/or thickness, or employment of a pi-type liquid crystal orientation.

In an active matrix liquid crystal display element, the operation of storing a voltage and a charge in the liquid crystal section is actually performed only in a period during which each scan line is selected (write time). The write time is $16.7 \mu\text{s}$ (microsecond) in the case of a liquid crystal display apparatus which has 1000 lines and in which an image signal for the 1000 lines is written within one field time, and about $5 \mu\text{s}$ in the case of a liquid crystal display apparatus which is driven in a field sequential scheme. Presently, no known liquid crystal element or known manner of liquid crystal completes its response within the time period as described above. Even among liquid crystal elements that cause spontaneous polarization and nematic liquid crystal of improved response speed, no known element exhibits such quick response. This results in the problem that response of liquid crystal generally occurs after completion of signal write operation. Consequently, in liquid crystal elements that cause spontaneous polarization, a depolarization field

is generated due to rotation of spontaneous polarization, so that voltages at opposite ends of a liquid crystal layer drop abruptly. Therefore, the voltages stored at the opposite ends of the liquid crystal layer change largely.

5 Meanwhile, in the high speed nematic liquid crystal, change in the capacitance of a liquid crystal layer caused by anisotropy of dielectric constant increases considerably, resulting in a change in the voltage that is written into the liquid crystal layer and must be held constant. Such
10 a decrease in the holding voltage; i.e., a decrease in the effective applied voltage, results in insufficient writing, so that the on-screen contrast decreases. Further, when the same signal is repeatedly written, the brightness continuously changes until lowering of the holding voltage
15 stops, so that a few frames are required to obtain stable brightness.

"Japanese Applied Physics," Vol. 36, Part 1, No. 2, pp 720 - 729 reports that a so-called "step response" phenomenon occurs when an identical image signal is
20 written over a few frames after a frame in which an image signal changes and thus the absolute value of a signal voltage changes. According to this phenomenon, for the same signal voltage, the transmittance of liquid crystal changes in the manner of damped oscillation over a few
25 frames, so that the liquid crystal becomes bright in

alternate frames and dark in other frames. After a few frames, the transmittance is stabilized at a predetermined level.

An example of the above phenomenon will be described with reference to Figs. 1-3. Fig. 1(a) is chart showing the waveform of a data voltage; and Fig. 1(b) is a chart showing change in transmittance at that time. When the data voltage shown in Fig. 1(a) is applied to liquid crystal, as shown in Fig. 1(b), the transmittance of liquid crystal changes in the manner of damped oscillation such that the liquid crystal becomes alternately light and dark. In the illustrated example, the transmittance of the liquid crystal converges to a constant level in the fourth frame. Since the liquid crystal requires a few frames to change its transmittance as described above, high speed display of images is impossible.

Fig. 2(a) is a chart showing the waveform of a data voltage; Fig. 2(b) is a chart showing change in a gate voltage; and Fig. 2(c) is a chart showing change in transmittance at that time. Fig. 3 is a timing chart for scan lines in the drive shown in Fig. 2. The color shade during each of positive and negative display periods 102 and 104 represents brightness corresponding to the transmittance of Fig. 2. In Fig. 3, a time period of 16.7 ms is indicated by an arrow.

Fig. 3 depicts six scan lines. Positive writing 101 is successively performed from the top scan line in order to obtain a positive display 102, and then negative writing 103 is successively performed from the top scan line in order to obtain a negative display 104. In each scan line, the period of the positive writing 101 and the period of the positive display 102 constitute a first field, while the period of the negative writing 103 and the period of the negative display 104 constitute a second field. The first and second fields constitute one frame.

When the data voltage of Fig. 2(a) is applied and a TFT switch is turned on by the gate voltage of Fig. 2(b), as shown in Fig. 2(c), the transmittance of liquid crystal changes in the manner of damped oscillation such that the liquid crystal becomes alternately light and dark. This is observed as flicker, which has the effect of deteriorating the quality of display. Further, as shown in Fig. 2(c), the transmittance of the liquid crystal converges to a constant level in the second frame (fourth field) following application of the signal voltage.

As a result, the brightness changes in an oscillating manner, as shown in Fig. 3. As described above, even when liquid crystal of high response speed is used, the speed of a display image decreases, because a few frames are required to stabilize the brightness.

The transmittance of liquid crystal after response is determined not by an applied signal voltage but by the amount of charge stored in the liquid crystal serving as a capacitor. The amount of charge depends on a total
5 amount of accumulated charge that exists before the signal is written and of charge that is newly written.

The amount of charge accumulated after response also changes depending on design values in relation to pixels such as the physical constants of liquid crystal, electric
10 parameters and an amount of charge accumulation.

Therefore, in order to establish correspondence between a signal voltage and transmittance, data, actual calculation, and the like are required for determining (1) the relationship between the signal voltage and an amount of
15 stored charge, (2) an amount of charge present before signal writing operation, and (3) an amount of charge present after response. Therefore, there becomes necessary a frame memory for storing the data regarding (2) for the entire screen, and a calculation section for
20 calculating the data (1) and (3). This is not preferred, because the number of parts of the system increases.

In order to solve the above problem, there is sometimes used a reset pulse scheme, in which a reset voltage is applied to liquid crystal so as to bring the liquid
25 crystal into a predetermined state before new data are

written therein.

As an example, a technique described in IDRC, pp. 66-69, 1997 will be described. This technique uses an OCB (optically compensated bi-refrignce) mode in which
5 nematic liquid crystal is aligned to obtain a pi-type alignment, and compensation film is attached to the liquid crystal. The response speed of the liquid crystal mode is about 2 to 5 msec, which is considerably faster than that of a conventional TN mode.

10 Although response is theoretically considered to be completed within one frame, as described above, a few frames are required for attainment of stable transmittance, because a holding voltage greatly decreases due to change in dielectric constant caused by
15 response of the liquid crystal. A method for solving this problem is shown in Fig. 5 of the above literature. In this method, within one frame, a signal for black display is always written after a signal for white display is written. Fig. 5 of the literature is reproduced as Fig. 4.
20 The horizontal axis represents time, while the vertical axis represents brightness. A dotted line shows variation in brightness for the case of ordinary drive and indicates that the brightness reaches a stable level in the third frame.

25 When the reset pulse scheme is employed, liquid

crystal always attains a predetermined state before new data are written therein, and one-to-one correspondence can be observed between a written signal voltage and an obtained transmittance. This one-to-one correspondence
5 simplifies the manner of generation of drive signals and obviates a frame memory or other means for storing previous written information.

In order to apply a reset voltage to liquid crystal, there is used another method which comprises the steps of
10 generating positive and negative data signal voltages for a certain image signal; applying to the liquid crystal the positive (negative) voltage and then the negative (positive) voltage; and subsequently applying a reset voltage to the liquid crystal. In this case, if the positive and negative
15 data signal voltages having the same amplitude are applied, the "step response" as described above occurs. Therefore, a data signal voltage having a waveform shown in Fig. 5(a) is applied to liquid crystal. Fig. 5(b) is a graph showing a variation in transmittance observed at
20 that time. The waveform of a data signal voltage whose negative and positive values have the same amplitude is indicated by a dotted line in Fig. 5(a), and a variation in transmittance when the data signal voltage of Fig. 5(a) is applied to liquid crystal is indicated by a dotted line in Fig.
25 5(b).

In order to avoid "step response," as shown in Fig. 5(a), the amplitude of a data voltage in a first half of a frame (a positive data voltage in this example) is made small, and the amplitude of the data voltage in a second half of the frame (a negative data voltage in this example) is made equal to that of the waveform indicated by the dotted line. This setting prevents step response, so that, as shown in Fig. 5(b), the same transmittance is obtained in the first and second halves of the frame. By the subsequent step of resetting the liquid crystal at the end of the frame, the liquid crystal is brought into a predetermined reset state. In a subsequent frame, a new signal voltage having a similar waveform is applied, so that the transmittance of the liquid crystal changes in accordance with the new signal voltage. In this manner, one-to-one correspondence is established between the constant signal voltage and the constant transmittance.

Further, in order to solve these problems, there has been proposed a drive method called "pseudo DC-drive" shown in AMLDC, 97 digest, pp. 119-122.

This technique will be described with reference to Figs. 6 and 7. Similar to Fig 2, Fig. 6(a) is a chart showing the waveform of a data voltage; Fig. 6(b) is a chart showing change in a gate voltage; and Fig. 6(c) is a chart showing change in transmittance at that time. Fig.

7 is a timing chart for each scan line, and the color shade in each of positive and negative display periods 102 and 104 represents brightness corresponding to the transmittance of Fig. 6(c). In Fig. 6, a time period of 16.7 ms is indicated by an arrow.

In the literature, a period of 16.7 ms is defined as one frame period. However, since this definition is not generally accepted, the period is changed in the drawings of the present specification (one frame period described in the literature corresponds to one field period used in the present specification with regard to ordinary conventional techniques).

In the "pseudo DC-drive" unlike the case of AC drive as shown in Fig. 2, a data voltage of the same polarity is continuously applied to liquid crystal over a plurality of fields. After the plurality of fields, the polarity of the data voltage is reversed so as to eliminate electrical imbalance. In Fig. 6, after positive writing over four fields, negative writing is performed over four fields to complete display of one image signal. Since writing is performed for each scan line at timing as shown in Fig. 7, an operation of successively writing positive data from the top line is repeated four times, and then an operation of successively writing negative data from the top line is repeated four times.

This method enables attainment of a state in which voltages held at opposite ends of liquid crystal become the same as a constant applied DC voltage. As a result, the holding voltage does not decrease due to response of liquid crystal, and the final transmittance becomes higher than that in the case of AC drive shown in Fig. 2, in which the holding voltage decreases due to response of liquid crystal.

However, in this method, one frame period becomes equal to the total of a plurality of frames of different polarities. That is, in the example shown in Fig. 6, the length of one frame is four times that of the frame in Fig. 2.

Even if any of the reset pulse schemes described above is employed, the conventional reset pulse method has the following problems. First, brightness changes greatly depending on position within a screen which is effected by the timing when the reset operation is performed. For example, when scanning is performed from the top of the screen toward the bottom of the screen, and the reset operation is performed after completion of scanning of all lines; at the top of the screen, a period substantially corresponding to one field is available as a display time after the writing operation, but at the bottom of the screen, only a very short time is available as the display time after the writing operation. This

phenomenon is described with reference to Fig. 8.

Fig. 8(a) schematically shows states in a write (scanning) period 101, a display period 102, and a reset period 103 in two dimensions; i.e., the scanning direction of a screen and time axis. In this Figure, eight scan lines are shown, and in the write period 101, scanning is performed successively from the top of the screen toward the bottom thereof. After the display period 102 having a predetermined length, the entire screen is reset at a time during the reset period 103. Fig. 8(b) schematically shows a scan line voltage and transmittance in the uppermost part of the display or on a first (No.1) scan line when white color is displayed by use of the drive method as described above. Fig. 8(c) schematically shows a scan line voltage and transmittance in the lowermost part of the display or on an eighth (No.8) scan line. In the first scan line, white is displayed during a relatively long period corresponding to a value equal to one frame period less the sum of the reset period and a transient response period. However, in the eighth scan line, since the reset is started simultaneously with the end of the response period, white cannot be displayed sufficiently. As a result, when the entire frame period is considered, as shown in Fig. 9B, there occurs a phenomenon that the top portion of the screen is bright and the bottom portion of the screen is

dark. Such a brightness variation within the screen deteriorates image quality considerably.

Next, since the period for bringing the liquid crystal into a predetermined display state always exists, the
5 overall contrast and the maximum transmittance decrease. For example, if the liquid crystal is reset such that the liquid crystal display turns to black, a period available for displaying a certain color other than black becomes shorter than that available when no reset operation is
10 performed, so that the maximum transmittance and the transmittance at each gradation both decrease. If the liquid crystal is reset such that the liquid crystal displays a color other than black, the transmittance at the time of the reset is added when black is displayed and is averaged
15 with respect to time, with the result that the transmittance at the time of black being displayed is increased, and the contrast decreases.

Further, since the period during which the transmittance of the liquid crystal attains a constant level
20 always exists, flicker is generated between that transmittance and a transmittance occurring at the time of another color being displayed. For example, when the entire screen is reset concurrently, flickering occurs over the entire screen, so that a great degree of flicker is
25 observed.

Moreover, the scanning period decreases by an amount corresponding to the length of the reset period.

In general, the scanning period (write time) is

substantially equivalent to a time obtained through

5 division of the field time, which is half the frame time, by

the number of scan lines. However, if a reset period is

provided in the field time, the scanning period 101 shown

in Fig. 8(a) decreases to a time obtained through division

of (the field time minus the reset time 103) by the number

10 (8) of scan lines. As a result, the scanning period

becomes shorter. In order to solve the problem that the

reset period affects the scanning period, there has been

proposed a method in which interlace drive is combined

with reset, as shown in, for example, Patent Publication

15 JP-A-92-186217. In this method, a FLC (ferroelectric

liquid crystal) panel is driven in an interlace mode, and

scan lines are reset in their respective non-display periods.

This prevents a decrease in the length of the scanning

period. Further, the reset timings of adjacent lines are

20 shifted from each other, and the degree of flicker is

considered to decrease due to averaging. However, even

when this method is used, the remaining problems, such

as variation of brightness within the screen and decrease

in the maximum transmittance, cannot be solved.

25 Meanwhile, in the pseudo DC-drive, as described

above, a longer frame period (in the example of Figs. 6 and 7, a period four times that of an AC drive) is required compared to the AC drive, so that high responsiveness of the liquid crystal cannot be exploited effectively.

5 Consequently, flicker of a long period, which fluctuates at a period a few times that of the ordinary frame period (16.7 ms), is generated of which brightness is shown in Fig. 7.

10 SUMMARY OF THE INVENTION

In view of the foregoing, an object of the present invention is to provide a method for driving a fast response liquid crystal display apparatus, which method decreases in-plane brightness difference and flicker
15 caused by employment of reset pulses, and which realizes high contrast and high brightness.

Another object of the present invention is to provide a liquid crystal display apparatus which is driven by the drive method and which has increased response speed,
20 contrast, and brightness, and reduced in-plane brightness difference and flicker.

Still another object of the present invention is to provide a method for driving a liquid crystal element which realizes one-to-one correspondence between an
25 applied signal voltage and transmittance without use of a

reset-pulse method or a frame memory.

Yet another object of the present invention is to provide a method for driving a liquid crystal element which realizes one-to-one correspondence between an applied signal voltage and transmittance and enables a high-speed response. A further object of the present invention is to provide liquid crystal display apparatuses that employ these drive methods.

In order to achieve the above objects, the present invention provides in a method for driving a liquid crystal display apparatus comprising the steps of scanning successively scan lines for display and resetting the scan lines in each field, the improvement wherein the scan lines are simultaneously reset after the scan lines are successively scanned in a first field, and the scan lines are simultaneously reset after the scan lines are successively scanned in a second field in an order reverse to that in the first field (hereinafter referred to as a first invention).

According to the liquid crystal driving method of the first invention, since the time from writing to reset can be averaged throughout a display panel, a uniform in-plane brightness variation is obtained.

When interlace drive is effected by the method of the first invention, preferably odd scan lines are scanned successively, e.g., from top to bottom, in a first frame, and

even scan lines are scanned successively in the reverse direction, e.g., from bottom to top, in a second frame.

When the interlace drive is employed, it is also preferred that in each frame, two write periods be
5 provided for each scan line and two reset periods be provided for each scan line. The method may be modified such that in each frame one reset period is provided for each scan line, and a data signal voltage used in a first writing operation after the reset has an absolute value
10 smaller than that of a data signal voltage used in a second writing operation.

According to the first invention, there can be realized a method which is suitable for a fast response liquid crystal display apparatus that uses reset pulses, which
15 can decrease in-plane brightness variation and flicker, while realizing high contrast and high brightness, and which is not affected by electrical asymmetry. Further, according to the first invention, a liquid crystal display apparatus and a field-sequential liquid crystal display
20 apparatus which employ the method of driving can be realized.

In order to achieve the above objects, the present invention also provides a method for driving a liquid crystal display element (hereinafter referred to as a first
25 method of driving), in which each frame comprises a first

field and a second field;

data are written a plurality of times in the first field by use of a predetermined signal voltage; and

data are written a plurality of times in the second
5 field by use of a signal voltage whose polarity is reversed (hereinafter referred to as a second invention).

Another method (hereinafter referred to as a second drive method) for driving a liquid crystal element according to the present invention is characterized in that
10 data are written a plurality of times in each frame by use of a signal whose polarity becomes alternately positive and negative at a predetermined frequency (hereinafter referred to as a third invention).

Third and fourth methods for driving are derived
15 from the second and third invention, respectively, and are characterized in that a group of scan lines are divided into a plurality of blocks, and the plurality of blocks are scanned simultaneously.

Further, each of fifth and sixth methods for driving is
20 employed by a field-sequential liquid crystal display apparatus in which each frame is divided into three fields corresponding to three colors, and data are successively written for display within each field, characterized in that

the method for driving each color is either the third
25 or fourth method for driving.

The first method for driving corresponds to the pseudo DC driving method in which the drive frequency is increased, whereby writing operation is performed a plurality of times within each field by AC drive.

5 The second method for driving corresponds to the AC method for driving in which the drive frequency is increased, whereby AC drive is performed a plurality of periods within each frame.

10 The third method for driving is a variation of the first method for driving and is characterized in that a group of scan lines are divided into a plurality of blocks, and the plurality of blocks are scanned simultaneously. The fourth method for driving is a variation of the second method for driving and is characterized in that a group of scan lines are divided into a plurality of blocks, and the plurality of blocks are scanned simultaneously.

15 The fifth method for driving derived from the second or third invention is for field sequential display and is characterized in that liquid crystal is driven in the same manner as in the first and third method for driving, and for each color, there are provided a plurality of positive writing operations, a display period subsequent thereto, a plurality of negative writing operations, and a display period subsequent thereto.

25 The sixth method for driving derived from the second

or third invention is for field sequential display and is characterized in that liquid crystal is driven in the same manner as in the second and third method for driving, and for each color, there are provided a plurality of AC drive
5 operations and a display period subsequent thereto.

A liquid crystal display apparatus according to the second or third invention is a liquid crystal display apparatus that utilizes the method for driving according to any one of the first to fourth methods for driving.

10 Another liquid crystal display apparatus according to the second or third invention is a field-sequential liquid crystal display apparatus that utilizes the method for driving according to the fifth or sixth method and is characterized in that view-angle dependency of liquid
15 crystal display mode and in-plane brightness variation caused by the method for driving are cancelled out.

According to the second and third invention, there can be realized a method for driving which is suitable for a fast response liquid crystal display apparatus which can
20 drive a liquid crystal element without use of reset pulses and without calculation between image data sets, which realizes high contrast and high brightness, and which is not affected by electrical asymmetry. Further, there are realized a liquid crystal display apparatus and a field-
25 sequential liquid crystal display apparatus which employ

the method for driving.

BRIEF DESCRIPTION OF THE DRAWINGS

5 Figs. 1(a) and 1(b) are charts for describing a step response in conventional fast response liquid crystal, wherein Fig. 1(a) shows the waveform of an applied voltage, and Fig. 1(b) shows variation in transmittance upon application of the applied voltage of Fig. 1(a).

10 Fig. 2 shows charts for describing the waveform of a data signal used in a conventional AC driving method, wherein Fig. 2(a) is the waveform of a voltage applied to a data line, Fig. 2(b) shows the waveform of a voltage applied to a gate line, and Fig. 2(c) shows variation in transmittance when the voltages of Figs. 2(a) and 2(b) are
15 applied to fast response liquid crystal.

Fig. 3 is a diagram showing the time chart for each scan line and the brightness of display for each scan line in the conventional AC driving method shown in Fig. 2.

20 Fig. 4 is a diagram showing a variation with time of brightness when a method using reset is applied to a conventional OCB mode.

Fig. 5 shows diagrams for describing the waveform of a data signal for prevention of a step response, wherein Fig. 5(a) shows the waveform of an applied voltage, and
25 Fig. 5(b) shows variation in transmittance upon

application of the voltage of Fig. 5(a).

Fig. 6 shows charts for describing the waveform of a data signal used in a conventional pseudo DC driving method, wherein Fig. 6(a) is the waveform of a voltage applied to a data line, Fig. 6(b) shows the waveform of a voltage applied to a gate line, and Fig. 6(c) shows variation in transmittance when the voltages of Figs. 6(a) and 6(b) are applied to fast response liquid crystal.

Fig. 7 is a diagram showing the time chart for each scan line and the brightness of display for each scan line in the conventional pseudo DC driving method shown in Fig. 6.

Fig. 8 is charts showing a conventional method for driving, wherein Fig. 8(a) is a time chart for each scan line, Fig. 8(b) shows the waveform of a voltage applied for a first scan line and variation in transmittance at that time, and Fig. 8(c) shows the waveform of a voltage applied for an eighth scan line and variation in transmittance at that time.

Fig. 9 is charts showing distribution of brightness within a panel surface driven by the conventional method, wherein Fig. 9A shows brightness distributions at times 1A - 1F in Fig. 8(a), and Fig. 9B shows brightness distribution averaged within a frame time.

Fig. 10 is charts showing the structure and operation

of a first embodiment of the present invention, wherein Fig. 10(a) shows a time chart for each scan line, Fig. 10(b) shows the waveform of a voltage applied for a first scan line and variation in transmittance at that time, and Fig.
5 10(c) shows the waveform of a voltage applied for an eighth scan line and variation in transmittance at that time.

Fig. 31 shows light-source brightness and a time chart for each scan line in a nineteenth embodiment.

Fig. 32 is a cross-sectional view showing a layered
15 structure of a liquid crystal display apparatus according to a twentieth embodiment.

Fig. 33 is charts for describing the operation of a liquid crystal display apparatus according to Example 6, wherein Fig. 33(a) is the waveform of a voltage applied to
20 a data line, Fig. 33(b) shows the waveform of a voltage applied to a gate line, and Fig. 33(c) shows variation in transmittance when the voltages of Figs. 33(a) and 33(b) are applied.

Fig. 34 is charts for describing the operation of a
25 liquid crystal display apparatus according to Example 7,

wherein Fig. 34(a) is the waveform of a voltage applied to a data line, Fig. 34(b) shows the waveform of a voltage applied to a gate line, and Fig. 34(c) shows variation in transmittance when the voltages of Figs. 34(a) and 34(b) are applied to liquid crystal.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Then, the present invention will be described in further detail by the description of embodiments and examples of the first invention with reference to the accompanying drawings. The same periods as those described in relation to the prior art are denoted by the same reference numerals and their detailed description will be omitted.

First Embodiment:

Fig. 10 is charts showing a method for driving according to a first embodiment of the first invention. Fig. 10(a) is a time chart showing time allotment for each scan line, wherein the horizontal axis is a time axis, and the vertical axis shows the positions of scan lines. Fig. 10(b) shows an exemplary case where eight scan lines are provided. Fig. 10(b) is a time chart showing the waveform of a voltage applied for the first scan line and variation in transmittance at that time, and Fig. 10(c) is a

time chart showing the waveform of a voltage applied for the eighth (final) scan line and variation in transmittance at that time.

In the present embodiment, scan lines are successively selected and data therefor are written into liquid crystal during a write period 101, and display is provided during a display period 102. Subsequently, all the scan lines are reset during a reset period 103. The sequence or order in which the scan lines are scanned in the first field of each frame is different from that in the second field of the frame. Specifically, in the first field, the scanning is performed downward from the first scan line to the eighth scan line, and in the second field, the scanning is performed upward from the eighth scan line to the first scan line. The scanning in the first and second fields may be performed in sequences opposite to the respective sequences described above.

As shown in Fig. 10(b), with respect to the first scan line, a scanning signal for writing is applied to the liquid crystal at the beginning of the first field, and a scanning signal for resetting is applied to the liquid crystal at the end of the first field. In the second field, a write signal is applied to the liquid crystal slightly before the end of the second field, and a reset signal is applied to the liquid crystal at the end of the second field. By contrast, as

shown in Fig. 10(c), with respect to the eighth scan line, a write signal is applied to the liquid crystal slightly before the end of the first field, and a reset signal is applied to the liquid crystal at the end of the first field. In the
5 second field, a write signal is applied to the liquid crystal at the beginning of the second field, and a reset signal is applied to the liquid crystal at the end of the second field. In the example shown in Figs. 10(b) and 10(c), the write signal has a level for displaying white (high
10 transmittance), and the reset signal has a level for displaying black (low transmittance). However, the transmittance resulting from the writing operation changes depending on actually written data.

With respect to the first scan line, the transmittance
15 starts to increase from the beginning of the first field, reaches the maximum after completion of the write operation, and decreases to the minimum during the reset period at the end of the field. In the second field, the transmittance starts to increase from a point slightly
20 before the end of the field, reaches the maximum after completion of the write operation, and decreases to the minimum during the reset period immediately after the transmittance has reached the maximum. By contrast, with respect to the eighth scan line, the transmittance
25 starts to increase from a point slightly before the end of

the first field, reaches the maximum after completion of the write operation, and decreases to the minimum during the reset period immediately after the transmittance has reached the maximum. In the second field, the
5 transmittance starts to increase from the beginning of the field, reaches the maximum after completion of the write operation, and decreases to the minimum during the reset period at the end of the field.

Fig. 11A shows a distribution of brightness within a
10 screen of a liquid crystal display panel driven by the method shown in Figs. 10(a) - 10(c). Screens 1A, 1B, and 1C respectively correspond to times 1A, 1B, and 1C shown in Fig. 10(a) and respectively show a brightness distribution at the beginning of the write period of the
15 first field, a brightness distribution at the later part of the write period of the first field, and a brightness distribution at the end of the first field. Similarly, screens 1D, 1E, and 1F respectively correspond to times 1D, 1E, and 1F shown in Fig. 10(a) and respectively show
20 a brightness distribution at the beginning of the write period of the second field, a brightness distribution at the later part of the write period of the second field, and a brightness distribution at the end of the second field. Fig. 11B shows an actually observed brightness distribution;
25 i.e., a brightness distribution averaged with respect to

time over the frame time. As shown in Fig. 11A, at times 1A and 1B of the first field, the top portion of the screen becomes brighter than the bottom portion thereof, reflecting the changes in transmittance shown in Fig.

5 10(c), and at times 1D and 1E of the second field, the bottom portion of the screen becomes brighter than the top portion thereof. Further, at times 1C and 1F at the ends of the respective fields, the entire screen becomes black. As described above, the brightness distribution
10 within the screen changes greatly every moment.

However, as is apparent from Fig. 11B, which shows the averaged brightness distribution, the brightness distributions at different moments are averaged, so that the observed brightness is uniform over the entire screen.

15

Second Embodiment:

Figs. 12(a) - 12(c) are time charts that show a second embodiment of the present invention in the same manner as in Figs. 10(a) - 10(c). In the present embodiment, bi-
20 directional scanning is performed as in the first embodiment. However, the present embodiment differs from the first embodiment in that the position of the reset period is changed from that in the first embodiment, and interlace drive is employed. In the present embodiment,
25 one half of the eight scan lines (odd-numbered scan lines,

hereinafter called "odd scan lines") are scanned (selected) in the first field, and the remaining half of the eight scan lines (even-numbered scan lines, hereinafter called "even scan lines") are scanned (selected) in the second field.

5 The reset period 103 for each scan line is positioned at the end of the field in which the scan line is not scanned (selected). Specifically, for odd scan lines, a write period 101 is provided in the first field such that these scan lines are successively scanned from the top for write operation,
10 followed by a display period 102. A reset period 103 is provided at the end of the second field. For even scan lines, a reset period 103 is provided at the end of the first field, and a write period 101 is provided in the second field such that these scan lines are successively scanned from
15 the bottom for write operation, followed by a display period 102. Another reset period is provided at the end of the first field of the next frame (unillustrated).

In the first field, the odd scan lines as counted from the top are successively scanned from the top, and in the
20 second field, the even scan lines as counted from the top are successively scanned from the bottom. Specifically, with respect to the first scan line, a write signal is applied to the liquid crystal at the beginning of the first field, and a reset signal is applied to the liquid crystal at the end of
25 the second field. Therefore, the transmittance starts to

increase from the beginning of the first field, reaches the maximum after completion of the write operation, and decreases to the minimum during the reset period at the end of the second field. By contrast, with respect to the eighth scan line, a reset signal is applied to the liquid crystal at the end of the first field, and a write signal is applied to the liquid crystal at the beginning of the second field. Therefore, the transmittance reaches the minimum at the end of the first field, starts to increase at the beginning of the second field, and reaches the maximum after completion of the write operation.

Figs. 13A and 13B show brightness distributions in a liquid crystal display panel of the second embodiment, in the same manner as in Figs. 11A and 11B. Screens 2A - 2F in Fig. 13A respectively correspond to times 2A - 2F shown in Fig. 12(a). In the first field, as shown in Fig. 13A, at the beginning and the end of the write period, the even scan lines are displayed such that they are always bright and the odd scan lines are displayed such that the top portion of the screen becomes brighter than the bottom portion thereof. In the second field, at the beginning and the end of the write period, the odd scan lines are displayed such that they are always bright and the even scan lines are displayed such that the bottom portion of the screen becomes brighter than the top

portion thereof. At the end of the first field, the even scan lines become black, and the odd scan lines become white. By contrast, at the end of the second field, the odd scan lines become black, and the even scan lines become
5 white. As described above, the brightness distribution within the screen changes greatly every moment.

However, as is apparent from Fig. 13B, which shows the averaged brightness distribution, the variation in brightness distribution within the screen is mitigated
10 greatly. Although stripes having different brightnesses and corresponding to the scan lines are formed at the top and bottom portions of the screen, such stripes are hardly formed at the central portion of the screen. Since the pitch of the scan lines is very small in an actual screen,
15 the brightnesses of the strips are averaged spatially, so that substantially uniform brightness is obtained over the entire screen.

The second embodiment has an advantage that the brightness becomes considerably high as compared with
20 the brightness obtained in the first embodiment and shown in Fig. 11B. Further, since flicker is generated at different timings between the odd lines and the even lines of the interlace drive, the degree of observed flicker decreases due to averaging between the lines. Further,
25 since there exists no period during which the entire screen

becomes black, the degree of flicker decreases further.

Third Embodiment:

Figs. 14(a) - 14(c) are time charts that show a third
5 embodiment of the present invention in the same manner
as in Figs. 10(a) - 10(c). In the present embodiment, bi-
directional scanning is performed in combination with
interlace drive as in the second embodiment. The
method for driving of the present embodiment can be
10 achieved through modification of the method for driving of
the second embodiment such that the frame frequency is
doubled. That is, as shown in Fig. 10(a), for odd scan
lines, a write period 101 is provided in a first half of the
first field such that these scan lines are successively
15 scanned from the top for write operation, followed by a
display period 102. A reset period 103 is provided at the
end of the first field. The second field is similarly divided
into these periods. By contrast, for even scan lines, a
reset period 103 is provided at the end of the first half of
20 the first field, a write period 101 is provided in the second
half of the first field such that these scan lines are
successively scanned from the bottom for write operation,
and a display period 102 follows. The second field is
similarly divided into these periods. Another reset period
25 is provided at the end of the first half of the first field of

the next frame (unillustrated).

As shown in Fig. 14(b), with respect to the first scan line, a write signal is applied to the liquid crystal at the beginning of the first field, a reset signal is applied to the liquid crystal at the end of the first field, a write signal is applied to the liquid crystal at the beginning of the second field, and a reset signal is applied to the liquid crystal at the end of the second field. Therefore, the transmittance starts to increase from the beginning of the first field, reaches the maximum after completion of the write operation, and reaches the minimum during the reset period at the end of the first field. The transmittance again starts to increase from the beginning of the second field, reaches the maximum after completion of the write operation, and reaches the minimum during the reset period at the end of the second field. As shown in Fig. 14(c), with respect to the eighth scan line, a reset signal is applied to the liquid crystal at the end of the first half of the first field, a write signal is applied to the liquid crystal at the beginning of the second half of the first field, a reset signal is applied to the liquid crystal at the end of the first half of the second field, and a write signal is applied to the liquid crystal at the beginning of the second half of the second field. Therefore, the transmittance reaches the minimum at the end of the first half of the

first field, starts to increase at the beginning of the second half of the first field, and reaches the maximum after completion of the write operation. The transmittance again reaches the minimum at the end of the first half of the second field, starts to increase at the beginning of the second half of the second field, and reaches the maximum after completion of the write operation.

Fig. 15A shows a brightness distribution actually observed and averaged in frame time in a liquid crystal display panel according to the third embodiment. The method for driving of the third embodiment mitigates variation in brightness which is observed on a screen of a liquid crystal display panel driven by the conventional method for driving of Fig. 9B. In the present embodiment, since the reset period is provided twice in each frame, the brightness obtained in the present embodiment is lower than that obtained in the second embodiment. Other characteristics are mostly the same as those obtained in the second embodiment. However, the present embodiment greatly differs from the second embodiment in terms of electrical asymmetry. According to the method for driving of the first embodiment shown in Fig. 10, in many cases the length of the display period 102 in the first field differs from that in the second field. Therefore, if the method for driving of the first

embodiment is used for liquid crystal that causes spontaneous polarization, such as ferroelectric liquid crystal or antiferroelectric liquid crystal, electrical asymmetry is likely to be produced due to depolarization field generated by polarized poles, which is a cause of image sticking stemming from ions. Further, in the method for driving of the second embodiment shown in Fig. 12, since the write period is provided only one time in each frame, electrical asymmetry is produced depending on the polarity of the written data signal. By contrast, in the present embodiment, the length of the display period in the first field is identical to that in the second field, and data signals of opposite polarities can be written for the first and second fields. Therefore, no electrical asymmetry is produced, and image sticking does not occur.

Fourth Embodiment:

Figs. 16(a) - 16(c) are time charts that show a fourth embodiment in the same manner as in Figs. 10(a) - 10(c). In the present embodiment, bi-directional scanning is performed in combination with interlace drive as in the second and third embodiments. However, the present embodiment differs from the second and third embodiments in that the interlace drive is performed within each of the first and second fields, but the scanning

direction in the second field is opposite to that in the first field. That is, for odd scan lines, a write period 101 is provided in a first half of the first field such that these scan lines are successively scanned from the top, followed
5 by a display period 102, and a reset period 103 is provided at the end of the first field. Subsequently, a write period 101 is provided in a first half of the second field such that these scan lines are successively scanned from the bottom, followed by a display period 102, and a reset period 103 is
10 provided at the end of the second field. By contrast, for even scan lines, a reset period 103 is provided at the end of the first half of the first field, and a write period 101 is provided in the second half of the first field such that these scan lines are successively scanned from the top,
15 followed by a display period 102. Subsequently, a reset period 103 is provided at the end of the first half of the second field, and a write period 101 is provided in the second half of the second field such that these scan lines are successively scanned from the bottom, followed by a
20 display period 102. Another reset period is provided at the end of the first half of the first field of the next frame (unillustrated).

As shown in Fig. 16(b), with respect to the first scan line, a write signal is applied to the liquid crystal at the
25 beginning of the first field, a reset signal is applied to the

liquid crystal at the end of the first field, a write signal is applied to the liquid crystal at a point slightly before the end of the second field, and a reset signal is applied to the liquid crystal at the end of the second field. Therefore,

5 the transmittance starts to increase from the beginning of the first field, reaches the maximum after completion of the write operation, and reaches the minimum during the reset period at the end of the first field. The transmittance again starts to increase at a point slightly

10 before the end of the first half of the second field, reaches the maximum after completion of the write operation, and reaches the minimum during the reset period at the end of the second field. As shown in Fig. 16(c), with respect to the eighth scan line, a reset signal is applied to the liquid

15 crystal at the end of the first half of the first field, a write signal is applied to the liquid crystal at a point slightly before the end of the second half of the first field, a reset signal is applied to the liquid crystal at the end of the first half of the second field, and a write signal is applied to the

20 liquid crystal at the beginning of the second half of the second field. Therefore, as shown in Fig. 16(c), the transmittance reaches the minimum at the end of the first half of the first field, starts to increase at the point slightly before the end of the second half of the first field,

25 and reaches the maximum after completion of the write

operation. The transmittance again reaches the minimum at the end of the first half of the second field, starts to increase at the beginning of the second half of the second field, and reaches the maximum after
5 completion of the write operation.

Fig. 15B shows a brightness distribution actually observed and averaged in frame time in a liquid crystal display panel according to the present embodiment. The method for driving of the present embodiment mitigates
10 variation in brightness which is observed in the conventional method for driving of Fig. 9B and the third embodiments of Fig. 15A. Consequently, stripes having different brightnesses observed in the second and third embodiments are not generated. Further, unlike in the
15 first embodiment shown in Fig. 11B in which no variation is generated in brightness within a screen, the degree of observed flickers can be decreased. That is, in the present embodiment, since flicker is generated at different timings between the odd lines and the even lines of the
20 interlace drive, the degree of observed flicker decreases due to averaging between the lines. Further, since there exists no period during which the entire screen becomes black, the degree of flicker decreases further. Moreover, since the effective frequency is higher than that in the
25 first embodiment of Fig. 10, the difference between the

length of the display period 102 in the first field and that in the second field decreases to about half that in the first embodiment, and the write operation can be performed twice in each frame. As a result, the difference between
5 the length of the display period 102 in the first field and that in the second field becomes very small, and data signals of opposite polarities can be written for the first and second fields. Therefore, electrical asymmetry is hardly produced, and the possibility of occurrence of
10 image sticking is small.

Fifth Embodiment:

Figs. 17(a) - 17(c) are time charts that show a fifth embodiment of the present invention in the same manner
15 as in Figs. 10(a) - 10(c). In the present embodiment, bi-directional scanning is performed in combination with interlace drive as in the second to fourth embodiments. However, in the present embodiment, bi-directional interlace drive is performed within each of the first and
20 second fields, and the scanning direction in the second field is made opposite to that in the first field. That is, for odd scan lines, a write period 101 is provided in a first half of the first field such that these scan lines are successively scanned from the top, followed by a display
25 period 102, and a reset period 103 is provided at the end

of the first field. Subsequently, a write period 101 is provided in a first half of the second field such that these scan lines are successively scanned from the bottom, followed by a display period 102, and a reset period 103 is provided at the end of the second field. By contrast, for even scan lines, a reset period 103 is provided at the end of the first half of the first field, and a write period 101 is provided in the second half of the first field such that these scan lines are successively scanned from the bottom, followed by a display period 102. Subsequently, a reset period 103 is provided at the end of the first half of the second field, and a write period 101 is provided in the second half of the second field such that these scan lines are successively scanned from the top, followed by a display period 102. Another reset period is provided at the end of the first half of the first field of the next frame (unillustrated).

As shown in Fig. 17(b), with respect to the first scan line, a write signal is applied to the liquid crystal at the beginning of the first field, a reset signal is applied to the liquid crystal at the end of the first field, a write signal is applied to the liquid crystal at a point slightly before the end of the second field, and a reset signal is applied to the liquid crystal at the end of the second field. Therefore, the transmittance starts to increase from the beginning of

the first field, reaches the maximum after completion of the write operation, and reaches the minimum during the reset period at the end of the first field. The transmittance again starts to increase at a point slightly before the end of the first half of the second field, reaches the maximum after completion of the write operation, and reaches the minimum during the reset period at the end of the second field. As shown in Fig. 17(c), with respect to the eighth scan line, a reset signal is applied to the liquid crystal at the end of the first half of the first field, a write signal is applied to the liquid crystal at the beginning of the second half of the first field, a reset signal is applied to the liquid crystal at the end of the first half of the second field, and a write signal is applied to the liquid crystal at a point slightly before the end of the second half of the second field. Therefore, the transmittance reaches the minimum at the end of the first half of the first field, starts to increase at the beginning of the second half of the first field, and reaches the maximum after completion of the write operation. The transmittance again reaches the minimum at the end of the first half of the second field, starts to increase at the point slightly before the end of the second half of the second field, and reaches the maximum after completion of the write operation. The brightness distribution actually observed and averaged in

frame time in a liquid crystal display panel of the present embodiment is the same as that shown in Fig. 15B for the fourth embodiment. Other features are the same as those of the fourth embodiment.

5

Sixth Embodiment:

Fig. 18(a) is a time chart that shows a sixth embodiment of the present invention in the same manner as in Figs. 10(a). In the present embodiment, bi-
10 directional scanning is performed in combination with interlace drive as in the second to fifth embodiments. However, the present embodiment employs the data signal voltage shown in Fig. 5 and differs from the previous embodiment in that two write period 101 and one reset
15 period 103 are provided in each frame. That is, for odd scan lines, a write period 101 is provided in a first half of the first field such that these scan lines are successively scanned from the top, followed by a display period 102. Subsequently, a write period 101 is provided in a first half
20 of the second field such that these scan lines are successively scanned from the top, followed by a display period 102, and a reset period 103 is provided at the end of the second field. By contrast, for even scan lines, a reset period 103 is provided at an intermediate point in
25 the first field, and a write period 101 is provided in the

second half of the first field such that these scan lines are successively scanned from the bottom, followed by a display period 102. Subsequently, a write period 101 is provided in the second half of the second field such that these scan lines are successively scanned from the bottom, followed by a display period 102. Another reset period is provided at an intermediate position in the first field of the next frame (unillustrated).

Fig. 18(b) shows a brightness distribution actually observed and averaged in frame time in the present embodiment. Although the method for driving of the present embodiment mitigates the variation in brightness distribution within the screen which is observed as shown in Fig. 9B when the conventional method for driving is employed, stripes having different brightnesses and corresponding to the scan lines are formed at the top and bottom portions of the screen. However, such stripes are hardly formed at the central portion of the screen. Since the pitch of the scan lines is very small in an actual screen, the brightnesses of the strips are averaged spatially, so that substantially uniform brightness is obtained over the entire screen. The brightness obtained in the present embodiment is considerably higher as compared with the conventional method for driving (Fig. 9B) and the first embodiment (Fig. 11B). Further, since the time between

the reset period and the next write period is shorter than that in the second embodiment, higher brightness is obtained. Moreover, since flicker is generated at different timings between the odd lines and the even lines
5 of the interlace drive, the degree of observed flicker decreases due to averaging between the lines. Further, since there exists no period during which the entire screen becomes black, the degree of flicker decreases further.

10 Seventh Embodiment:

Fig. 18(c) is a time chart that shows a seventh embodiment of the present invention in the same manner as in Fig. 10(a). The present embodiment is almost the same as the sixth embodiment, but differs therefrom in
15 terms of the scanning direction in the second field. Bi-directional scanning is performed in combination with interlace drive as in the second to fifth embodiments. That is, for odd scan lines, a write period 101 is provided in a first half of the first field such that these scan lines
20 are successively scanned from the top, followed by a display period 102. Subsequently, a write period 101 is provided in a first half of the second field such that these scan lines are successively scanned from the bottom, followed by a display period 102, and a reset period 103 is
25 provided at the end of the second field. By contrast, for

even scan lines, a reset period 103 is provided at an intermediate point in the first field, and a write period 101 is provided in the second half of the first field such that these scan lines are successively scanned from the bottom, followed by a display period 102. Subsequently, a write period 101 is provided in the second half of the second field such that these scan lines are successively scanned from the top, followed by a display period 102. Another reset period 103 is provided at an intermediate position in the first field of the next frame (unillustrated). The time averaged brightness distribution is the same as that shown in Figs. 18(b) for the sixth Embodiment.

Eighth Embodiment:

Fig. 19A is a time chart showing an eighth embodiment of the present invention. The present embodiment premises the provision of field-sequential display. Therefore, in addition of the time chart of Fig. 10(a), Fig. 19A shows brightness radiated from a light source to a display panel as one vertical axis. The light source is scanned in turn of red, green, and blue, in this drawing. The color sequence may be changed freely together with a corresponding change in the sequence of data signals. The light from the light source does not enter the panel during the reset period, during which the

color of the light is changed. Although the scanning is performed in the same timing as that in the case where the data signal voltage shown in Fig. 5 is used, three reset periods 103 are provided in each frame, because of the field sequential display. Two write periods 101 are provided within each scanning period for each color, and positive and negative data signals are distributed and applied to each write period by every polarity. A reset period 103 is provided after the two write periods. The period set including two write periods and one reset period is repeated three times synchronously with the change of color. As a result of the change of color and the scanning of scan lines, information for the respective colors is displayed within one frame, so that color can be displayed at pixel level. Since the number of the reset periods becomes half that in the case in which the conventional method for driving shown in Fig. 8 is repeated three times to effect field sequential display, brighter display is enabled. The observed brightness distribution becomes the same as that shown in Fig. 9B, in which the lower portion of the screen is displayed more darkly.

Ninth Embodiment:

Fig. 19B is a time chart showing a ninth embodiment

of the present invention in the same manner as in Fig. 19A. As in the eighth embodiment, the color of light is scanned among red, green, and blue, in this sequence.

The color sequence may be changed freely together with a
5 corresponding change in the sequence of data signals.

The present embodiment differs from the eighth
embodiment in that light from the light source does not
enter the liquid crystal not only during the reset period
but also during a period including the first write period
10 after the reset period and a period required for
stabilization of display, and such an extended period is
used for switching the color among three colors. That is,
after completion of a transition period in which the entire
screen from the top portion to the lower portion of the
15 panel is changed from the reset state to a new display
state, the light source radiates light to the liquid crystal
panel in order to allow an observer to view the displayed
color image. This method eliminates variation in
brightness within the screen observed in the eighth
20 embodiment, so that uniform brightness is obtained over
the entire screen. Fig. 20 is a time chart showing time
allotment for light-source colors and time allotment for
each scan line in a method for driving for eliminating
variation in brightness within a panel surface driven by a
25 conventional field-sequential liquid crystal display

apparatus. In the conventional method for driving, light is radiated from the light source to the liquid crystal panel when the reset operation is completed and display of a written image becomes stable. Therefore, the period of time during which the light source is turned on is very short. By contrast, in the present embodiment, since the period during which the light source is in an on state is long, the brightness over the entire screen becomes higher.

10 Tenth Embodiment:

Fig. 21 is a time chart showing a tenth embodiment of the present invention in the same manner as in Fig. 18(a). The light source is scanned among red, green, and blue, in this sequence. The color sequence may be changed freely together with a corresponding change in the sequence of data signals. Although the scanning is performed in the same timing as that of the bi-direction scanning of the first embodiment as shown in Fig. 10, three reset periods 103 are provided in each frame because of the field sequential display. Two write periods 101 are provided within each scanning period for each color, and positive and negative data signals are distributed and applied to each write period by every polarity. The first and second write periods 101 correspond to scanning from the top and scanning from

the bottom of the bi-directional scanning. In Fig. 21, when the color of light is red, for example, the scanning from the top is first performed, followed by a reset period, the scanning from the bottom, and another reset period, in this sequence. In this manner, the period set including two write periods and two reset periods is repeated three times synchronously with the change of color. Herein, a period including one write period and one reset period is called a "sub field." First and second sub fields are present for each color, and a field set including these sub fields is repeated three times to constitute one frame. The light source is turned on at the beginning of the first sub field and is turned off immediately before the reset period of the second sub field. During the reset period, the color is changed. As a result of the scanning of color and the scanning of scan lines, information for the respective colors is displayed within one frame, so that color display can be displayed at the pixel level. Since the present embodiment employs bi-directional scanning as in the first embodiment, adjustment of the on-period of the light source as in the ninth embodiment becomes unnecessary, and the variation in brightness within the screen is eliminated. Further, since the period during which the light source is in an on state is longer than that in the conventional method shown in Fig. 20, the

brightness becomes higher than that obtained in the conventional method. Whereas the light source must be turned on and off each sub field in the conventional method shown in Fig. 20, such on-and-off operation is
5 unnecessary in the present embodiment.

Eleventh Embodiment:

An eleventh embodiment of the present invention is directed to a liquid crystal display apparatus that employs
10 any one of the methods for driving according to the first through seventh embodiments. Fig. 22 is a plan view of a liquid crystal display apparatus according to the present embodiment, showing an array of TFTs (thin-film transistors 12) on one substrate. The substrate of the
15 present embodiment includes a TFT substrate and an opposite substrate. As shown in Fig. 22, the TFT substrate has a plurality of gate bus lines 13, a plurality of drain bus lines 11, and an array composed of a plurality of TFTs 12. At least one pixel electrode 14 is provided for
20 each pixel. Fig. 23 is a schematic view showing a section of the liquid crystal display apparatus of the present embodiment. An electrode 17 is formed on each of two support substrates 16, and an orientation film 18 for orientating liquid crystal is formed thereon. Liquid
25 crystal 19 is held between the support substrates 16, and

a pair of polarization plates 15 are provided on the outer surfaces of the support substrates 16.

The operation of the present embodiment is as follows. A data signal having a waveform corresponding to a selected method for driving is applied to each drain bus line 11 at a predetermined frequency. Further, a signal having a waveform shown in the respective embodiments and capable of turning on the TFT 12 is applied to each gate bus line 13 when the gate bus line 13 is selected. Thus, the voltage on the drain bus line 11 is applied to the liquid crystal via the display electrode. The applied voltage is held in the liquid crystal until the gate bus line 13 is selected again. This enables the operation of holding a display if the liquid crystal has no ability of storing. For reset operation, a predetermined reset signal is applied to the drain bus line 11, and a voltage for turning on the TFT 12 is applied to the gate bus line 13 at the timing shown in the respective embodiments. Through the above operation, the liquid crystal display apparatus is driven by the method for driving according to any one of the first through seventh embodiments of the present invention.

Twelfth Embodiment:

A liquid crystal display apparatus according to a

twelfth embodiment of the present invention has a structure similar to that shown in Fig. 23 and is driven by any one of the methods for driving of the eighth to tenth embodiments. An electrode 17 is formed on each of two support substrates 16, and an orientation film 18 for orientating liquid crystal is formed thereon. Liquid crystal 19 is held between the support substrates 16, and a pair of polarization plates 15 are provided on the outer surfaces of the support substrates 16. Further, an unillustrated light source for field sequential display is provided adjacent to one of the polarization plates 15. Thus, there is obtained a liquid crystal display apparatus that is driven by the method for driving according to any one of the eighth through tenth embodiments of the present invention.

Thirteenth Embodiment:

A liquid crystal display apparatus according to the thirteenth embodiment of the present invention has an improvement over the eleventh embodiment or the twelfth embodiment. The liquid crystal display apparatus of the present embodiment has a structure for canceling out or generally mitigating the viewing angle dependency of the liquid crystal and the variation in brightness within a screen caused by the method for driving. Due to this

structure, the viewing angle dependency of the liquid crystal and the variation in brightness within a screen caused by the method for driving is mitigated, so that the liquid crystal display apparatus of the present
5 embodiment provides excellent display.

Next, there will be described specific examples of the liquid crystal display apparatus to which the above-mentioned embodiments of the first invention are applied.

10 Example 1:

Chromium (Cr) was sputtered to form 480 gate bus lines and 640 drain bus lines each having a width of 10 μm . A gate insulating film was formed by use of silicon nitride (SiN_x). Each pixel had a length of 330 μm and a
15 width of 110 μm . TFTs (thin-film transistors) were formed by use of amorphous silicon, and transparent electrodes serving as pixel electrodes were formed of indium tin oxide (ITO) through sputtering. A glass substrate on which TFTs had been formed in an array was
20 used as a first substrate. A second substrate to be disposed opposite to the first substrate was formed as follows. A light shielding film of chromium was formed on a glass plate, and transparent electrodes (common electrodes) of ITO were formed thereon. Subsequently, a
25 color filter was formed in a matrix shape by use of a

staining technique, and a protective layer of silica was formed thereon. Subsequently, soluble polyimide was printed by means of a printing method, and the substrate was then baked at 180°C in order to remove the solvent.

5 Through use of a rubbing apparatus in which rayon buff cloth is wound around a roller having a diameter of 50 mm, the polyimide film was rubbed such that parallel rubbing was performed twice under the following conditions: roller rotational speed of 600 rpm, stage feed
10 speed of 40 mm/sec, and press amount of 0.7 mm. The thickness of the orientation film measured through use of a contact-type step meter was about 500 angstroms, and the pre-tilt angle measured by a crystal rotation method was 7 degrees. Micro pearls having a diameter of about
15 9.5 μm and serving as spherical spacers were dispersed on one of the glass substrates, and an ultraviolet-hardening-type seal material in which cylindrical rod spacers made of glass and having a diameter of about 9.5 μm had been dispersed was applied to the other glass plate. These
20 plates were disposed such that they faced each other and their directions of rubbing became parallel to each other. Subsequently, ultraviolet rays were radiated in a non-contacting manner in order to cure the seal material, thereby completing a panel having a gap of 9.5 μm , into
25 which nematic liquid crystal was injected. In the present

embodiment, a compensation plate was added in order to operate the panel in an OCB (optically compensated birefringence) display mode described in SID 94, digest, pp. 927-930. A driver was attached to the thus-fabricated liquid crystal panel in order to complete the liquid crystal display apparatus.

The method for driving of the first embodiment was applied to the above-described liquid crystal display apparatus. Specifically, the length of the reset period 103 was set to 5 msec, the length of the write period for each scan line was set to 15 μ sec, and the length of each field was set to 16.7 msec. As result, a display period of about 4.5 msec was secured in one field, even for the last-scanned scan line. Further, a display period of about 16 msec was obtained when the two display periods of the bi-directional scanning were added. Although the rising response speed of the liquid crystal depends on the applied voltage, the response is completed within a few to 5 msec, i.e., after writing operation. The liquid crystal panel provided a wide view angle and has no dependency on the viewing angle. When the liquid crystal display apparatus was observed, no variation in brightness was observed within the panel, and therefore, a wide view angle was obtained by taking advantage of the characteristics of the liquid crystal display mode

providing the wide view angle.

Example 2:

A TFT substrate and a color filter substrate were
5 fabricated in the same manner as in Example 1.

Subsequently, polyamic acid was applied thereon by a spin
coat method, and these substrates were baked at 200°C in
order to form polyimide film through imidation. Through
use of a rubbing apparatus in which Nylon buff cloth is
10 wound around a roller having a diameter of 50 mm, the
polyimide film was rubbed such that cross rubbing was
performed twice under the following conditions: roller
rotational speed of 600 rpm, stage feed speed of 40 mm/sec,
press amount of 0.7 mm, and rubbing cross angle of 10°.

15 The thickness of the orientation film measured through
use of a contact-type step meter was about 500 angstroms,
and the pre-tilt angle measured by a crystal rotation
method was 1.5 degrees. Micro pearls having a diameter
of about 2 μm and serving as spherical spacers were
20 dispersed on one of a pair of glass substrates, and a
thermosetting seal material in which cylindrical rod
spacers made of glass and having a diameter of about 2
 μm had been dispersed was applied to the other glass
plate. These plates were disposed such that they faced
25 each other and their directions of rubbing intersected each

other at angle of 10° . Subsequently, the seal material was hardened through heat treatment, thereby completing a panel having a gap of $2\text{ }\mu\text{m}$.

Antiferroelectric liquid crystal performing V-shaped

5 switching disclosed in Asia Display 95, pp 61-64 was injected in an isotropic phase (Iso) state into the panel at 85°C under vacuum. While the temperature was

maintained at 85°C , a rectangular wave having an amplitude of $\pm 10\text{ V}$ and a frequency of 3 kHz was applied

10 to the entire surface of the panel through use of an arbitrary waveform generator and a high output amplifier in order to apply a field to the liquid crystal. In this state, the liquid crystal panel was gradually cooled to room temperature at a rate of $0.1\text{ }^\circ\text{C}/\text{min}$. A driver was
15 attached to the thus-fabricated liquid crystal panel in order to complete the liquid crystal display apparatus.

The method for driving of the fifth embodiment was applied to the above-described liquid crystal display apparatus. Specifically, the length of the reset period 103

20 was set to 1 msec , the length of the write period for each scan line was set to $10\text{ }\mu\text{sec}$, the length of each field was set to 16.7 msec , and the length of each frame period was set to 33.4 msec . As result, a display period of about 10 msec was secured in one field, even for the last-scanned

25 scan line. Further, a display period of about 25 msec was

obtained when the two display periods in the bi-directional scanning were added. Although the rising response speed of the liquid crystal depends on the applied voltage, the response is completed within a few
5 hundreds μsec , i.e., after writing operation. The liquid crystal panel provided a wide view angle and has no dependency on the viewing angle. When the liquid crystal display apparatus was observed, no variation in brightness was observed within the panel, and therefore,
10 a wide view angle was obtained by taking advantage of the characteristics of the liquid crystal display mode proving the wide view angle.

Example 3:

15 The same liquid crystal panel as that used in Example 2 was used. A driver and a high-speed swichable back light were combined with the liquid crystal panel to fabricate a field-sequential liquid crystal display apparatus.

20 The drive of the liquid crystal display apparatus and the scanning of brightness of a light source were performed in the manner of the tenth embodiment. Specifically, the length of the reset period 103 was set to 1 msec, the length of the write period for each scan line was
25 set to 5 μsec , and the length of each frame period was set

to 33.4 msec. As result, a display period of about 6.5 msec was secured for each color. Further, no variation in brightness was observed within the panel.

5 Comparative Example 1:

The same field-sequential liquid crystal display mode as that used in Example 3 was used. The conventional method for driving (Fig. 20) of the liquid crystal display apparatus and field-sequential liquid crystal display
10 apparatus using the scanning of brightness of a light source were employed. Although no variation in brightness was observed within the panel as in Example 3, the display period for each color was about 4 msec, and the panel brightness was about half that obtained in
15 Example 3.

Example 4:

A micro display was fabricated as a reflection type projector. The micro display had a similar structure as
20 that of a micro display produced by Displaytech Corp. described at the beginning of Advanced Imaging, January, 1997. Specifically, MOS FETs were formed on a silicon wafer in accordance with a 0.8 μm rule in order to fabricate a DRAM. The die size was 1/2 inch, the pixel
25 pitch was 10 μm , and the capacity of the DRAM was 1M

bits. The aperture ratio of the pixel was 90% or higher. Further, the surface of the fabricated DRAM was made flat by use of a chemical mechanical polishing technique.

A cover glass for microscope observation was used as an
5 opposite substrate. A portion including a drive circuit was cut from a silicon wafer, and orientation film formed of soluble polyimide was printed. Subsequently, the substrate was baked at 170°C in order to remove the solvent. Through use of a rubbing apparatus in which

10 Nylon buff cloth is wound around a roller having a diameter of 50 mm, the polyimide film was rubbed twice under the following conditions: roller rotational speed of 600 rpm, stage feed speed of 40 mm/sec, and press amount of 0.7 mm. The thickness of the orientation film

15 measured through use of a contact-type step meter was about 500 angstroms, and the pre-tilt angle measured by a crystal rotation method was 1.5 degrees. A light-

curing-type seal material in which cylindrical rod spacers made of glass and having a diameter of about 2 μm had

20 been dispersed was applied to each of the glass plates.

These plates were disposed such that they faced each other, and ultraviolet rays were radiated in a non-contacting manner in order to cure the seal material, thereby completing a panel having a gap of 2 μm .

25 Subsequently, antiferroelectric liquid crystal composition

performing V-shaped switching disclosed in Asia Display 95, pp 61-64 was injected in an isotropic phase (Iso) state into the panel at 85°C under vacuum. While the temperature was maintained at 85°C, a rectangular wave having an amplitude of ± 10 V and a frequency of 3 kHz was applied to the entire surface of the panel through use of an arbitrary waveform generator and a high output amplifier. In this state, the liquid crystal panel was gradually cooled to room temperature at a rate of 0.1 °C/min. while applying an electric field. Further, three light emitting diodes of three colors, a collimate lens for obtaining parallel light, a polarization conversion element, and a projection lens were combined to complete a reflection type field-sequential projector.

This liquid crystal display apparatus was driven by the method for driving of the ninth embodiment. As a result, excellent display in which no variation in brightness was obtained.

Fifth Embodiment:

A TFT substrate and a color filter substrate were fabricated in the same manner as in Example 1. Subsequently, film of soluble polyimide was printed, and the substrate was baked at 180°C in order to remove the solvent. Through use of a rubbing apparatus in which

rayon buff cloth is wound around a roller having a diameter of 50 mm, the polyimide film was rubbed such that 90° rubbing was performed twice under the following conditions: roller rotational speed of 600 rpm, stage feed speed of 40 mm/sec, press amount of 0.7 mm, and rubbing cross angle of 90°. The thickness of the orientation film measured through use of a contact-type step meter was about 500 angstroms, and the pre-tilt angle measured by a crystal rotation method was 3 degrees. Micro pearls having a diameter of about 5.5 μm and serving as spherical spacers were dispersed on one of a pair of glass substrates, and a light-curing-type seal material in which cylindrical rod spacers made of glass and having a diameter of about 5.5 μm had been dispersed was applied to the other glass plate. These plates were disposed such that they faced each other and their directions of rubbing intersected each other at angle of 90°. Subsequently, ultraviolet rays were radiated in a non-contacting manner in order to cure the seal material, thereby completing a panel having a gap of 5.5 μm , into which nematic liquid crystal was injected. In the present embodiment, a TN-type liquid crystal panel was fabricated. A driver was attached to the thus-fabricated liquid crystal panel in order to complete the liquid crystal display apparatus.

This liquid crystal display apparatus was driven by

the conventional method for driving shown in Fig. 8.

However, the orientation of the TN-type liquid crystal panel having a viewing angle dependency in the vertical direction was adjusted such that a higher brightness was obtained when observed from the upper side and a lower brightness was obtained when observed from the lower side of the panel. As a result, when the panel was observed from the front, variation in brightness in the screen caused by the method for driving and the viewing angle dependency were canceled out each other, so that display better than that of a conventional panel was obtained.

Then, the present invention will be described in further detail by the description of embodiments and examples of the second and third invention with reference to the accompanying drawings.

Fourteenth Embodiment:

The present embodiment is an example of a first method for driving a liquid crystal display element according to the present invention. Fig. 24(a) shows the waveform of a voltage applied to a data line, Fig. 24(b) shows the waveform of a voltage applied to a gate line, and Fig. 24(c) shows variation in transmittance when the voltages of Figs. 24(a) and 24(b) are applied to fast

response liquid crystal.

From one point of view, the present embodiment corresponds to a pseudo DC driving method utilizing an increased frequency, and from another point of view, it
5 corresponds to a method for driving in which writing operation is performed a plurality of times within each field by AC drive. Specifically, the voltage applied to a data line shown in Fig. 24(a) has a rectangular waveform, whose period corresponds to one frame composed of two
10 fields each having a length of 16.7 ms, as in the AC drive of Fig. 2. Meanwhile, the voltage applied to the gate line of Fig. 24(b) includes a plurality of (four in Fig. 24(b)) on-pulses during each field.

As a result, as shown in Fig. 24(c), the transmittance
15 increases gradually within one field (16.7 ms) with the progress of writing operations, and reaches a stable state during the fourth writing operation.

Fig. 25 is a chart showing a timing chart and display brightness for scan lines according to the first method for
20 driving. Fig. 25 shows the case where six scan lines are provided. The display brightness is shown by way of color shade.

As shown in Fig. 25, while the scan lines are successively scanned from the top, operation of writing a
25 positive data signal is repeated four times to form a first

field, and then while the scan lines are successively scanned from the top, operation of writing a negative data signal is repeated four times to complete a second field.

The first field and second field constitute one frame.

5 The length of the first field is 16.7 ms. As is apparent from Fig. 24(c), which shows the transmittance, the brightness increases with the number of writing operations within the same field. When the writing operation is performed n times within one field, the writing time for each scan
10 line becomes $1/n$ the writing time of an ordinary method for driving.

Fifteenth Embodiment:

The present embodiment is another example of a
15 second method for driving a liquid crystal display element according to the present invention. Fig. 26(a) shows the waveform of a voltage applied to a data line, Fig. 26(b) shows the waveform of a voltage applied to a gate line, and Fig. 26(c) shows variation in transmittance when the
20 voltages of Figs. 26(a) and 26(b) are applied to fast response liquid crystal.

The present embodiment corresponds to an AC drive method utilizing an increased frequency. Specifically, the voltage applied to a data line shown in Fig. 26(a) has a
25 rectangular waveform whose frequency is a few times (two

times in Fig. 26(a)) that in Fig. 2. Meanwhile, the voltage applied to the gate line show in Fig. 26(b) includes a single on-pulse during each field. Each field corresponds to each of positive and negative portions of the voltage waveform of Fig. 26(a). As a result, as shown in Fig. 26, four fields are present within each frame.

In the present embodiment, as shown in the variation of transmittance of Fig. 26(c), a step response is generated in response to a write signal within a period of 16.7 ms, so that the amplitude of vibration is gradually decreased, and a stable state is attained during the fourth writing operation.

Fig. 27 is a chart showing a timing chart and display brightness for scan lines. Fig. 27 shows the case where six scan lines are provided. The display brightness is shown by means of color shade. As shown in Fig. 27, while the scan lines are successively scanned from the top, a positive data signal is written to form a first field, and then, while the scan lines are successively scanned from the top after the reverse of the data signal voltage, a negative data signal is written to form a second field. Further, while the scan lines are successively scanned from the top, a positive data signal is written to form a third field, and then, while the scan lines are successively scanned from the top after the reverse of the data signal

voltage, a negative data signal is written to form a fourth field.

The first through fourth fields constitute one frame. The length of the first field is 8.35 ms. As is apparent from the graph of Fig. 26(c) showing the transmittance, the
5 brightness is changed in an oscillating manner within the frame and becomes stable at the end of the frame. When AC drive is effected n times within one field, the write time for each scan line becomes $1/n$ the writing time of an
10 ordinary AC drive method.

Sixteenth Embodiment:

The present embodiment is an example of a third method for driving a liquid crystal display element
15 according to the present invention. Fig. 28 is a chart showing a timing chart and display brightness for scan lines.

As in the fourteenth embodiment, the same data signal is written a plurality of times within one field in
20 the present invention. The present embodiment differs from the fourteenth embodiment in terms of the scanning method. In the present embodiment, a plurality of scan lines are simultaneously selected during scanning. As shown in Fig. 28, a group of scan lines are divided into
25 upper and lower blocks, and scanning is performed such

that, in each of the upper and lower blocks, lines are successively selected from top to bottom.

As a result, for each scan line, a period twice that in the fourteenth embodiment can be secured for writing operation. When AC drive is effected n times within one field and the scan lines are divided into m blocks, the write time for each scan line becomes m/n the writing time of an ordinary AC drive method.

10 Seventeenth Embodiment:

The present embodiment is an example of a fourth method for driving a liquid crystal display element according to the present invention. Fig. 29 is a chart showing a timing chart and display brightness for scan lines.

As in the fifteenth embodiment, AC drive is effected a plurality of times within one frame in the present embodiment. The present embodiment differs from the fifteenth embodiment in terms of the scanning method. In the present embodiment, during scanning a plurality of scan lines are selected simultaneously. As shown in Fig. 29, a group of scan lines are divided into upper and lower blocks, and scanning is performed such that, in each of the upper and lower blocks, lines are successively selected from top to bottom.

As a result, for each scan line, a period twice that in the fifteenth embodiment can be secured for writing operation. When AC drive is effected n times within one field and the scan lines are divided into m blocks, the
5 write time for each scan line becomes m/n the writing time of an ordinary AC drive method.

Eighteenth Embodiment:

The present embodiment is an example of a fifth
10 method for driving a liquid crystal display element according to the present invention. Fig. 30 is a chart showing a timing chart and display brightness for scan lines, thereby showing a time allotment for light source brightness and a time allotment for each scan line.

15 As in the fourteenth embodiment, the same data signal is written a plurality of times within one field in the present embodiment. Further, scanning is performed in the same manner as in the sixteenth embodiment. The present embodiment differs from the fourteenth and
20 sixteenth embodiments in that the present embodiment employs field sequential drive. Also, a constant display period 105 is provided in each field. Fig. 30 shows an exemplary case where twelve scan lines are provided.

Each frame is divided into three fields corresponding
25 to colors, and AC drive is effected within each field.

Further, writing operation is performed a plurality of times within each of positive and negative periods of the AC drive.

Meanwhile, the scan lines are divided into a plurality
5 of blocks, and during scanning a plurality of scan lines are simultaneously selected. As shown in Fig. 30, the scan lines are divided into four blocks, and scanning is performed such that, in each of the blocks, the uppermost scan lines are selected and written simultaneously and
10 the lines are successively selected from top to bottom. This scanning is repeated four times in order to continuously write a signal of a single polarity (positive in this case). Subsequently, a display period 105 is provided. The polarity of the data signal is reversed, and an
15 operation for simultaneously scanning the four blocks is repeated four times, such that a negative writing 103 ends, after which a display period 105 is provided.

At this time, the light source is maintained in an on state during a period including the display period, and is
20 maintained in an off state during a period in which the transmittance is unstable. Through this procedure, the first field is formed to complete display of red. Fields for green and blue are displayed in a similar manner. The three fields form a single frame.

Nineteenth Embodiment:

The present embodiment is an example of a sixth method for driving a liquid crystal display element according to the present invention. Fig. 31 is a chart
5 showing a timing chart and display brightness for scan lines, thereby showing a time allotment for light source brightness, and a time allotment for each scan line.

As in the fifteenth embodiment, AC drive is effected a plurality of times within one field in the present
10 embodiment. Further, scanning is performed in the same manner as in the seventeenth embodiment. The present embodiment differs from the fifteenth and seventeenth embodiments in that the present embodiment employs field sequential drive. Also, a constant display period
15 105 is provided in each field.

Fig. 31 shows an exemplary case where twelve scan lines are provided. Each frame is divided into three fields corresponding to three colors, and AC drive is effected within each field. Further, AC drive is
20 performed a plurality of times.

Meanwhile, the scan lines are also divided into a plurality of blocks, and a plurality of scan lines are simultaneously selected during scanning. As shown in Fig. 31, the scan lines are divided into four blocks, and
25 scanning is performed such that each of the blocks are

successively selected from top to bottom. This scanning is repeated four times in order to perform AC drive for two periods. Subsequently, a display period 105 is provided.

At this time, the light source is maintained in an on state during a period including the display period, and is maintained in an off state during a period in which the transmittance is unstable. Through this procedure, the first field is formed to complete display of red. Fields for green and blue are displayed in a similar manner. The three fields form a single frame.

Twentieth Embodiment:

The present embodiment is an example of a liquid crystal display apparatus of the present invention, which employs any one of the drive methods according to the fourteenth through seventeenth embodiments. Fig. 32 is a schematic view showing an example of the structure of a liquid crystal display apparatus to which the drive method of the present invention is applied, and is substantially identical with that of Fig. 23.

In the liquid crystal display apparatus of the present embodiment, an electrode 17 is formed on each of two support substrates 16, and an orientation film 18 for orienting liquid crystal is formed thereon. Liquid crystal 19 is held between the support substrates 16, and a pair of

polarization plates are provided on the outer surfaces of the support substrates 16. Thus, a liquid crystal display apparatus is constituted.

Next, the operation of the present embodiment will
5 be described. A data signal having a waveform
corresponding to a selected drive method is applied,
corresponding to each of gate lines, to each drain bus line
at a predetermined frequency. Further, a signal having a
waveform shown in the respective embodiment and
10 capable of turning on an active element is applied to each
gate bus line when the gate bus line is selected. Thus,
the voltage on the drain bus line is applied to the liquid
crystal via the display electrode. The applied voltage is
held in the liquid crystal until the gate bus line is selected
15 again. This enables the operation of holding a display if
the liquid crystal does not have an ability of storing. For
reset operation, a predetermined reset signal is applied to
the drain line, and a voltage for turning on the active
element is applied at the timing shown in the respective
20 embodiment.

Employment of the above structure enables
realization of a liquid crystal display apparatus to which
the drive method according to any one of the first through
fourth embodiments of the present invention is applied.

Twenty-first Embodiment:

The present embodiment is an example of a liquid crystal display apparatus of the present invention, which employs any one of the drive methods according to the
5 eighteenth and nineteenth embodiments.

In the liquid crystal display apparatus of the present embodiment, an electrode is formed on each of two support substrates, and an orientation film for orienting liquid crystal is formed thereon. Liquid crystal is held
10 between the support substrates, and a pair of polarization plates are provided on the outer surfaces of the support substrates. Further, a light source for field sequential display is provided in the vicinity of one polarization plate.

This constitution realizes a liquid crystal display
15 apparatus to which the drive method of the eighteenth or nineteenth embodiment is applied.

Next, the second and third inventions will be described in detail with reference to examples. However,
20 the present invention is not limited to the following examples.

Example 6:

The present example is an example of the liquid crystal display apparatus according to the present
25 invention. In the present example, chromium (Cr) lines

each having a width of 10 μm were formed by sputtering to provide 480 gate bus lines and 640 drain bus lines. A gate insulating film was formed by use of silicon nitride (SiN_x).

5 Each pixel had a length of 330 μm and a width of 110 μm . TFTs (thin-film transistors) were formed from amorphous silicon, and transparent electrodes serving as pixel electrodes of indium tin oxide (ITO) were formed through sputtering. The glass substrate on which TFTs
10 had been formed in an array was used as a first substrate.

A second substrate to be disposed opposite to the first substrate was formed as follows. A light-shielding film of chromium was formed on a glass plate, and transparent electrodes (common electrodes) of ITO were formed
15 thereon. Subsequently, a color filter was formed in a matrix shape by use of a staining technique, and a protective layer of silica was formed thereon. Subsequently, soluble polyimide was printed, and the substrate was baked at 180°C in order to remove the
20 solvent. Subsequently, polyamic acid was applied thereon by a spin coat method, and the substrates were baked at 200°C in order to form polyimide film through imidation.

Through use of a rubbing apparatus in which Nylon
25 buffing cloth is wound around a roller having a diameter

of 50 mm, the polyimide film was rubbed such that cross rubbing was performed twice under the following conditions: roller rotational speed of 600 rpm, stage feed speed of 40 mm/sec, pressing amount of 0.7 mm, and
5 rubbing cross angle of 10° .

The thickness of the orientation film was about 500 angstroms, as measured through use of a contact-type step meter, and the pre-tilt angle was 1.5 degrees, as measured by a crystal rotation method.

10 Micro pearls having a diameter of about $2\ \mu\text{m}$ and serving as spherical spacers were dispersed on one of the glass substrates, and a thermosetting seal material in which cylindrical rod spacers made of glass and having a diameter of about $2\ \mu\text{m}$ had been dispersed was applied to
15 the other glass plate. These plates were disposed such that they faced each other and their directions of rubbing intersected at an angle of 10° . Subsequently, the seal material was hardened through heat treatment, thereby completing a panel having a gap of $2\ \mu\text{m}$.

20 Antiferroelectric liquid crystal composition performing V-shaped switching disclosed in Asia Display 95, pp 61-64 was injected in an isotropic phase (Iso) state into the panel at 85°C under vacuum.

The value of spontaneous polarization of this liquid
25 crystal was $165\ \text{nC}/\text{cm}^2$, as measured through application

of a triangular waveform. Although the response speed varied depending on a gradation voltage, it was 200 to 800 μsec . While the temperature was maintained at 85°C , a rectangular wave having an amplitude of $\pm 10\text{ V}$ and a frequency of 3 kHz was applied to the entire surface of the panel through use of an arbitrary waveform generator and a high output amplifier. In this state, the liquid crystal panel was gradually cooled to room temperature at a rate of $0.1^{\circ}\text{C}/\text{min}$. while an electric field was applied.

A driver IC was attached to the thus-fabricated liquid crystal panel in order to complete the liquid crystal display apparatus.

The drive method of the first embodiment was applied to the above-described liquid crystal display apparatus. Specifically, the length of each field was set to 16.7 msec, the length of each frame period was set to 33.4 msec, the length of the write period for each scan line was set to $4.2\text{ }\mu\text{sec}$, and writing operation was performed eight times during each field.

Fig. 33 shows the waveform of an applied voltage and a change in transmittance measured for one pixel. Fig. 33(a) is a voltage applied to a drain, Fig. 33(b) is a voltage applied to a gate, and Fig. 33(c) shows variation in transmittance.

In the present example, since the degree of

spontaneous polarization of liquid crystal was large, the variation of the holding ratio caused by the response of crystal after writing operation was large. Consequently, the number of writing operations required for obtaining a stable transmission coefficient increased to 8, which is greater than that in the fourteenth embodiment.

The present method enables realization of a liquid crystal display apparatus of a high-speed response in which response for obtaining all intermediate gradations ends within one field even when a reset pulse method is not used and no frame memory is provided.

Example 7:

The present example is another example of the liquid crystal display apparatus according to the present invention. In the present example, a TFT substrate and a CF (color filter) substrate were fabricated in the same manner as in Example 6, and a panel was assembled in the same manner as in Example 6. Liquid crystal composition disclosed in Japanese Patent Application No. 97-093853 was injected in an isotropic phase (Iso) state into the panel at 85°C under vacuum. The composition of the liquid crystal was adjusted such that the value of spontaneous polarization of the liquid crystal composition became about 20 nC/cm². The value of spontaneous

polarization of this liquid crystal actually was 19.5 nC/cm^2 , as measured through application of a triangular waveform. Although the response speed varied depending on a gradation voltage, it was between $600 \text{ } \mu\text{sec}$ and 2 msec .

5 After injection, the panel was cooled to room temperature at a rate of $0.1 \text{ } ^\circ\text{C/min}$.

A driver IC was attached to the thus-fabricated liquid crystal panel in order to complete the liquid crystal display apparatus.

10 The liquid crystal display apparatus was driven by the drive method of the fourteenth embodiment. Specifically, the length of each field was set to 16.7 msec , the length of each frame period was set to 33.4 msec , the length of the write period for each scan line was set to
15 $11.5 \text{ } \mu\text{sec}$, and writing operation was performed three times during each field. Fig. 34 shows the waveform of an applied voltage and a change in transmittance measured for one pixel. Fig. 34(a) shows a voltage applied to a drain, Fig. 34(b) shows a voltage applied to a
20 gate, and Fig. 34(c) shows variation in transmittance.

In the present example, since the degree of spontaneous polarization of liquid crystal was small, the variation of the holding ratio caused by the response of crystal after writing operation was small. Consequently,
25 the number of writing operations required for obtaining a

stable transmission coefficient decreased to 3, which was smaller than that in the fourteenth embodiment. When the number of required writing operations decreases, decrease of the writing period can be suppressed as
5 compared with the case of Example 6. At the same time, the increase of the frequency of the drive circuit is suppressed, so that the cost of the drive circuit is lowered.

It is to be noted that even though the response speed of the liquid crystal itself was lower than that in Example
10 6, the time required to reach a stable state was shorter than that in Example 6 when the drive method of the present example was used. As in Example 6, the present method enables realization of a liquid crystal display apparatus of high-speed response in which response for
15 obtaining all intermediate gradations ends within one field even when a reset pulse method is not used and no frame memory is provided.

Example 8:

20 The present example is a further example of the liquid crystal display apparatus according to the present invention. In the present example, a TFT substrate was fabricated in the same manner as in Example 6. A second substrate to be disposed opposite to the first
25 substrate was formed as follows. A light-shielding film of

chromium was formed on a glass plate, a color filter was formed by an ink-jet scheme in which bubbles of dye were jetted, and an ITO film was formed thereon, on which a protective layer of silica was formed.

5 Through use of a rubbing apparatus in which rayon buffer cloth is wound around a roller having a diameter of 50 mm, the polyimide film was rubbed such that parallel rubbing was performed two times under the following conditions: roller rotational speed of 600 rpm, stage feed
10 speed of 40 mm/sec, and pressing amount of 0.7 mm.

The thickness of the orientation film was about 500 angstroms, as measured through use of a contact-type step meter, and the pre-tilt angle was 7 degrees, as measured by a crystal rotation method. Micro pearls
15 having a diameter of about 9.5 μm and serving as spherical spacers were dispersed on one of the glass substrates, and an ultraviolet hardening-type seal material in which cylindrical rod spacers made of glass and having a diameter of about 9.5 μm had been dispersed
20 was applied to the other glass plate.

These plates were disposed such that they faced each other and their directions of rubbing became parallel to each other. Subsequently, ultraviolet rays were radiated in a non-contacting manner in order to cure the seal
25 material, thereby completing a panel having a gap of 9.5

μm.

Nematic liquid crystal was injected into this panel. In the present embodiment, a compensation plate was added in order to operate the panel in an OCB (optically
5 compensated bi-refrignce) display mode described in SID 94, digest, pp. 927-930.

A driver was attached to the thus-fabricated liquid crystal panel in order to complete the liquid crystal display apparatus. Although the response speed varied
10 depending on a gradation voltage, it was 1.5 to 4 msec.

The drive method of the fourteenth embodiment was applied to the above-described liquid crystal display apparatus. Specifically, the length of each field was set to 16.7 msec, the length of each frame period was set to
15 33.4 msec, the length of the write period for each scan line was set to 11.5 μsec, and writing operation was performed three times during each field. The applied waveform was similar to that of Fig. 34. Since the response speed of the liquid crystal itself is lower than that in Example 7, the
20 response in relation to transmission coefficient is also slightly low.

However, since the number of writing operations required to reach a stable state was low, the time required to reach the stable state was shorter as compared with the
25 liquid crystal display apparatus of Example 6, whose

response speed was about five times faster. As in Examples 6 and 7, the present method enables realization of a liquid crystal display apparatus of high-speed response in which response for obtaining all intermediate gradations ends within one field even when a reset pulse
5 method is not used and no frame memory is provided.

Example 9:

The present example is yet another example of the liquid crystal display apparatus according to the present
10 invention. In the present example, a liquid crystal panel was fabricated in the same manner as in Example 7, and a driver was attached to the panel in order to obtain a liquid crystal display apparatus. The liquid crystal
15 display apparatus was driven by the drive method of the fifteenth embodiment.

In the present example, the writing time for each writing operation could be made longer than that in Example 7.

20

Example 10:

The present example is still another example of the liquid crystal display apparatus according to the present invention. In the present example, a liquid crystal panel
25 was fabricated in the same manner as in Example 7, and

a driver was attached to the panel so as to obtain a liquid crystal display apparatus. The liquid crystal display apparatus was driven by the drive method of the seventeenth embodiment.

5 In the present example, the writing time for each writing operation could be made longer than that in Example 9, so that no difference was observed between the present example and an ordinary AC drive.

As a result, an inexpensive, high performance liquid
10 crystal display apparatus was realized without use of elements for high frequency operation.

Example 11:

The present example is still another example of the
15 liquid crystal display apparatus according to the present invention. A liquid crystal panel used in the present example has the same structure as that of the liquid crystal panel used in Example 7. A driver and a backlight that was switchable at high speed were attached
20 to the panel to obtain a field-sequential liquid crystal display apparatus.

The drive of the liquid crystal display apparatus and the scanning of brightness of a light source were performed in the same manner as in the eighteenth
25 embodiment. Specifically, writing operation for each

polarity was performed four times, and the scan lines were divided into two blocks. The display period 105 was set to 2 msec, the length of the write period for each scan line was set to 3.5 μ sec, and the length of each frame
5 period was set to 33.3 msec. At that time, within each frame, two on-periods of 2.5 msec; i.e., a total on period of 5 msec, could be secured for each color in order to turn on the light source.

10 Example 12:

The present example is a still further example of the liquid crystal display apparatus according to the present invention. A liquid crystal panel used in the present example has the same structure as that of the liquid
15 crystal panel used in Example 7. A driver and a back light that was switchable at high speed were attached to the panel to obtain a field-sequential liquid crystal display apparatus.

The drive and the liquid crystal display apparatus
20 and the scanning of brightness of the light source were performed in the same manner as in the nineteenth embodiment. Specifically, AC drive was effected twice within each frame, and the scan lines were divided into two blocks. The display period 105 was set to 7.7 msec,
25 the length of the write period for each scan line was set to

3.5 μ sec, and the length of each frame period was set to 33.3 msec. At that time, within each frame, two on-periods of 2.5 msec; i.e., a total on-period of 8 msec could be secured for each color in order to turn on the light source,
5 which was longer than in Example 6.

Example 13:

The present invention is a yet further example of the liquid crystal display apparatus according to the present
10 invention. In the present example, a micro display was fabricated as a reflection type projector. The micro display had a similar structure as that of a micro display produced by Displaytech Corp. described at the beginning of Advanced Imaging, January, 1997.

15 Specifically, MOS FETs were formed on a silicon wafer in accordance with a 0.8 μ m rule in order to fabricate a DRAM. The die size was 1/2 inch, the pixel pitch was 10 μ m, and the capacity of the DRAM was 1M bits. The aperture ratio of the pixel was 90% or higher.
20 Further, the surface of the fabricated DRAM was made flat by use of a chemical mechanical polishing technique. A cover glass for microscope observation was used as the opposite substrate.

A portion including a drive circuit was cut from a
25 silicon wafer, and orientation film formed of soluble

polyimide was printed. Subsequently, the substrate was baked at 170°C in order to remove the solvent. Through use of a rubbing apparatus in which Nylon buff cloth is wound around a roller having a diameter of 50 mm, the polyimide film was rubbed twice under the following conditions: roller rotational speed of 6000 rpm, stage feed speed of 40 mm/sec, and press amount of 0.7 mm.

The thickness of the orientation film measured through use of a contact-type step meter was about 500 angstroms, and the pre-tilt angle measured by a crystal rotation method was 1.5 degrees.

A light-curing-type seal material in which cylindrical rod spacers made of glass and having a diameter of about 2 μm had been dispersed was applied. These substrates were disposed such that they faced each other, and ultraviolet rays were radiated in a non-contacting manner in order to cure the seal material, thereby completing a panel having a gap of 2 μm . Subsequently, antiferroelectric liquid crystal composition performing V-shaped switching disclosed in Asia Display 95, pp 61-64 was injected in an isotropic phase (Iso) state into the panel at 85°C under vacuum.

While the temperature was maintained at 85°C, a rectangular wave having an amplitude of ± 10 V and a frequency of 3 kHz was applied to the entire surface of the

panel through use of an arbitrary waveform generator and a high output amplifier. In this state, the liquid crystal panel was gradually cooled to room temperature at a rate of 0.1 °C/min. while an electric field was applied.

- 5 Further, three light emitting diodes of three colors, a collimate lens for obtaining parallel light, a polarization conversion element, and a projection lens were combined to complete a reflection type field sequential projector.

10 The liquid crystal display apparatus is driven by the drive method of the nineteenth embodiment. As a result, a projector display of high response speed was obtained.

Although preferred embodiments and examples of the present invention have been described above, the liquid crystal drive methods and liquid crystal display
15 apparatus of the invention are not limited thereto, and those obtained by changing or modifying the structures of the embodiments and examples are also encompassed by the scope of the present invention.
